Supporting Information

ABSTRACT: We show that the cooperation of lead thiocyanate additive and a solvent annealing process can effectively increase the grain size of mixed-cation lead mixed-halide perovskite thin films while avoiding excess lead iodide formation. As a result, the average grain size of the wide-bandgap mixed-cation lead perovskite thin films increases from 66 ± 24 to 1036 ± 111 nm, and the mean carrier lifetime shows a more than 3-fold increase, from 330 ns to over 1000 ns. Consequently, the average open-circuit voltage of wide-bandgap perovskite solar cells increases by 80 (70) mV, and the average power conversion efficiency (PCE) increases from 13.44 ± 0.48 (11.75 ± 0.34) to 17.68 ± 0.36 (15.58 ± 0.55)% when measured under reverse (forward) voltage scans. The best-performing wide-bandgap perovskite solar cell, with a bandgap of 1.75 eV, achieves a stabilized PCE of 17.18%.

Recently, organic–inorganic hybrid lead (Pb) halide perovskite polycrystalline thin-film solar cells have shown the unusual ability to produce both high open-circuit voltage ($V_{oc}$) and high power conversion efficiency (PCE).1–5 The high $V_{oc}$ in this case is with respect to the bandgap of the absorber, with an alternative parameter to assess the $V_{oc}$ being called the $V_{oc}$ deficit, defined by $E_g/q - V_{oc}$ where $E_g$ is the bandgap and $q$ is the elementary charge. Pb halide perovskite solar cells with $E_g$’s smaller than 1.66 eV have shown remarkably small $V_{oc}$ deficits; most of them are comparable with that of single-crystalline silicon (Si) solar cells and epitaxial gallium arsenide (GaAs) thin-film solar cells.6–10 The small $V_{oc}$ deficits are partially attributed to the unique defect tolerance properties of Pb halide perovskites, as revealed by density functional theory (DFT) calculations.11–13 Pb halide perovskites also exhibit excellent bandgap tunability. By varying the ratio of bromine (Br) to iodine (I), $E_g$ of Pb perovskites with mixed halides can be tuned from 1.58 to 2.20 eV.14 Importantly, the $V_{oc}$ deficit does not significantly increase as $E_g$ increases,13 making wide-bandgap perovskites extremely suitable for the top cell application in tandem solar cells. Efficient tandem solar cells have been fabricated by combining wide-bandgap perovskite top cells with Si, copper indium gallium diselenide (CIGS), polymer, and perovskite-based low-bandgap bottom cells.8,9,15–22 So far, the best-performing wide-bandgap Pb halide perovskite solar cell material is reported by Snaith and co-workers and has a composition of FA$_{0.83}$Cs$_{0.17}$Pb(I$_{0.6}$Br$_{0.4}$)$_3$ (FA = HC(NH$_2$)$_2$ (formamidinium), Cs = cesium) ($E_g$ = 1.74 eV). The best-performing cell has a $V_{oc}$ deficit of 0.54 V ($V_{oc}$ = 1.2 V) and a stabilized PCE of 16%.14 While this performance is excellent, further improvements are needed in order to produce more efficient tandem solar cells. It was reported that incorporating a small amount of Cs is critical for improving the stability of wide-bandgap perovskites containing mixed I and Br. However, adding Cs can significantly reduce the grain size of perovskite thin films, as reported in the literature,15 which may limit the device performance.

Two types of film modification approaches, either physical or chemical in nature, have been employed to increase the grain size...
of perovskite thin films. The physical approaches include “blowing-gas”,24 “solvent annealing”,25 “non-wetting substrate”,26 “hot-casting”,27 and “vacuum-flash”.28 The chemical approaches include a solvent-engineering process29 and adding additives such as hypophosphorus acid (HPA),30 MACI (MA = CH3NH3 (methylammonium)),31,32 and lead thiocyanate (Pb(SCN)).23,33,35 While the Pb(SCN)2 additive improves the grain size of mixed-cation (FA and Cs) Pb mixed-halide (Br and I) perovskite films that exhibit wide bandgaps, it has an undesirable side effect, that is, the formation of excessive lead iodide (PbI2).23,35 While the formation of a small amount of PbI2 may be beneficial,23,36,37,38 extensive PbI2 deteriorates the device performance.23,35 This dilemma limits the effectiveness of the Pb(SCN)2 additive approach for significantly improving the device performance of wide-bandgap mixed-cation Pb mixed-halide perovskite solar cells.

In this work, we report the synergistic effects of Pb(SCN)2 additive and solvent annealing on the performances of wide-bandgap mixed-cation Pb mixed-halide perovskite solar cells with the regular cell configuration. We show that the cooperation of 1.0 mol % Pb(SCN)2 additive and solvent annealing can effectively increase the grain size while avoiding the formation of excessive PbI2. As a result, the average grain size of wide-bandgap FA0.8Cs0.2PbI3 perovskite thin films (Eg = 1.75 eV) increased from 66 ± 24 to 1036 ± 317 nm, and the mean carrier lifetime showed a more than 3-fold increase, from 330 to over 1000 ns. Consequently, the average Voc of the resulting FA0.8Cs0.2PbI3 perovskite solar cells increased by 80 (70) mV and the average PCE increased from 13.44 ± 0.48 (11.75 ± 0.34) to 17.68 ± 0.36 (15.58 ± 0.53)% when measured under reverse (forward) voltage scans. The best-performing FA0.8Cs0.2PbI3 solar cell achieved a stabilized PCE of 17.18%. Through detailed characterizations, we find that the improvement in solar cell performance is primarily attributed to the enlarged grain size and improved crystallinity of wide-bandgap perovskite thin films.

First we examined the relationship of composition and bandgap for mixed-cation (FA and Cs) Pb mixed-halide (Br and I) perovskite thin films produced by the antisolvent dripping process described in our earlier work.23,33,34,35 On the basis of the results reported by Snaithe and co-workers,14 we fixed the FA/Cs molar ratio to be 0.8:0.2 while varying the Br content, giving a general composition of FA0.8Cs0.2PbI3-xBrx. We synthesized FA0.8Cs0.2PbI3-xBrx perovskite thin films with x = 0.0, 0.1, 0.2, 0.3, 0.4, and 0.5. The thin films were deposited on bare glass or glass/FTO/ALD-SnO2 substrates, and our solar cells have the regular cell configuration of glass/FTO/ALD-SnO2/C60:perovskite/spiro-OMeTAD/Au. Here, FTO is fluorine-doped tin oxide (SnO2:F), serving as the front electrode. ALD (atomic layer deposition)-SnO2 serves as the electron-selective layer (ESL). C60:perovskite is a fullerene self-assembled monolayer and serves as an interface passivation layer. Spiro-OMeTAD is 2,2’,7,7’-tetrakis(N,N-bis(p-methoxy-phenyl) amino)-9,9’-spirobifluorene and serves as the hole-selective layer (HSL). Au is gold and serves as the back contact. Consistent with reports in the literature,8,14 we found no phase separation for all compositions, as seen in the X-ray diffraction (XRD) patterns (Figure S1a).

The bandgap increases as the Br content increases, as shown in Figure S1b–d. We found that FA0.8Cs0.2PbI3 thin films have rather small grains, as revealed by scanning electron microscopy (SEM) (Figure S2). The average grain size increases slightly as the Br content increases. However, the average grain size is only 66 ± 24 nm (measured by ImageJ software) for the perovskite thin film with a composition of FA0.8Cs0.2PbI1-xBrx that exhibits the most suitable Eg of ~1.75 eV for the top cell application in tandem cells with the highest predicted PCEs.36,39 The resultant solar cell based on FA0.8Cs0.2PbI1-xBrx thin film showed an average PCE of 13.44 ± 0.48 (11.75 ± 0.34)% and an average Voc deficit of 0.60 ± 0.01 (0.66 ± 0.02) V when measured under reverse (forward) voltage scans.

Our previous work has shown that Pb(SCN)2 additive in perovskite precursor solution can significantly improve the grain size and, therefore, device performance. MAPbI3 and MAPbBr3 perovskite solar cells.30,31,32,33,34 Here, we examined the effect of Pb(SCN)2 additive on grain sizes of wide-bandgap FA0.8Cs0.2PbI3 thin films. The scanning electron microscopy (SEM) images given in Figures S3 and atomic force microscopy (AFM) images given in Figure S4 show that adding a small amount of Pb(SCN)2 additive in the perovskite precursor solution does increase the grain sizes of FA0.8Cs0.2PbI3 thin films; the grain size increases as the concentration of Pb(SCN)2 additive increases. XRD patterns shown in Figure S5a suggest that the perovskite films still exhibit a single perovskite phase. Figure S5b shows the photoluminescence (PL) spectra measured from these films, indicating no significant change in their bandgap values. The average grain size as a function of the amount of Pb(SCN)2 additive, as measured from the SEM images (Figure S3), is plotted in Figure S5c. The enlargement in grain size is very clear and significant. Though the grain size increases dramatically, the root-mean-square (RMS) roughness of FA0.8Cs0.2PbI3 thin film only slightly increases, as shown in Figure S5d as measured from the AFM images (Figure S4). Unfortunately, there is a serious adverse side effect for film synthesis using Pb(SCN)2 additives, that is, the formation of excessive PbI2 precipitates (identified by X-ray energy dispersive spectroscopy). When the amount of Pb(SCN)2 additive is increased to 2.0 mol %, large PbI2 nanorods are seen on the top of perovskite thin films (Figure S3e). We found that though the perovskite films have larger grains, the formation of large PbI2 nanorods can deteriorate the device performance. As shown in Figure S6 and Table S1, the amount of Pb(SCN)2 additive increases, all average device photovoltaic parameters such as Voc, the short-circuit current (Jsc), the fill factor (FF), and, therefore, the PCE, first increase, reach maximum values at 1.0 mol % Pb(SCN)2 additive, and then decrease. The maximum average PCE is 16.46 ± 0.37 (14.30 ± 0.65)% measured under reverse (forward) voltage scans, which is much higher than that of FA0.8Cs0.2PbI3 thin films (13.44 ± 0.48 (11.75 ± 0.34)%). These results encouraged us to keep exploring approaches to further increase the grain size and eliminate the formation of excessive PbI2.

We then explored the possibility of using solvent annealing to increase the grain size of FA0.8Cs0.2PbI3 thin films. In our solvent annealing process, the as-deposited perovskite thin films with and without Pb(SCN)2 additives were annealed at 65 °C for 2 min and then 100 °C for 5 min. During the entire annealing process, the thin films were covered by a glass Petri dish with the presence of 10 μL dimethylformamide (DMF). As shown in Figure 1a,b, solvent annealing can also increase the average grain size, from 66 ± 24 to 227 ± 103 nm. The grain size enlargement is slightly smaller than the use of 1.0 mol % Pb(SCN)2 additive, shown in Figure 1c. The average PCE of the devices fabricated using solvent annealing is 15.10 ± 0.38 (12.49 ± 0.36)%
Figure 1. (a–d) Top-view SEM images of FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} perovskite thin films synthesized using four different approaches: (a) no Pb(SCN)\textsubscript{2} additive and no solvent annealing; (b) no Pb(SCN)\textsubscript{2} additive with solvent annealing; (c) with 1.0 mol % Pb(SCN)\textsubscript{2} additive but no solvent annealing, and (d) with combined 1.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing. (e) Cross-sectional SEM image of the device with the perovskite layer synthesized by the combined 1.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing process. The white grains in (c) are PbI\textsubscript{2} precipitates.

measured under reverse (forward) voltage scans, which is slightly higher than that of the solar cells without solvent annealing and no Pb(SCN)\textsubscript{2} additive but slightly lower than the average PCE of the solar cells using 1.0 mol % Pb(SCN)\textsubscript{2} additive.

Surprisingly, we found that the combination of 1.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing (Figure S7) led to a significantly increased grain size (from 66 \pm 24 to 1036 \pm 317 nm), while avoiding the formation of excessive PbI\textsubscript{2} for FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} thin films, as shown in Figure 1d. As shown in Figure 1e, the average grain size becomes much larger than the film thickness after applying the combination of 1.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing. Although the exact mechanism of the structural evolution during the growth and annealing process is not known yet, a recent paper by Zhou et al. provided some useful insights.\textsuperscript{40} That is, while the Pb(SCN)\textsubscript{2} additive may form CH\textsubscript{3}NH\textsubscript{2} gas, which can enlarge perovskite grains,\textsuperscript{33} the presence of DMF vapor may promote coarsening by Ostwald ripening in competition with nucleation. It is worth noting that even with such large enhancement in grain size, the perovskite thin films are still smooth, with an average RMS roughness of 19.14 \pm 0.90 nm, measured by AFM. The XRD patterns (Figure S8a) show that the FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} thin film without Pb(SCN)\textsubscript{2} additive or solvent annealing (labeled as 0% Pb(SCN)\textsubscript{2}) has the same Domains of ±30°, the film with only Pb(SCN)\textsubscript{2} additive (labeled as 1% Pb(SCN)\textsubscript{2}) has a slightly (101) preferred orientation. However, the film with combined Pb(SCN)\textsubscript{2} additive and solvent annealing (labeled 1% Pb(SCN)\textsubscript{2} + SA) shows a slightly (100) preferred orientation. The growth mechanism for the films with combined Pb(SCN)\textsubscript{2} additive and solvent annealing is still unknown but is worth exploring in further studies. Furthermore, optical absorbance and PL emission measurements show that the combined 1.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing do not significantly change the bandgap of the FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} absorber thin films, as seen in Figure S8b. Therefore, the FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} perovskite thin films after applying combined 1.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing maintain a E\textsubscript{g} of 1.75 eV and exhibit large grains, smooth surface, and without excessive PbI\textsubscript{2} precipitates, which are highly desirable features for fabricating efficient thin-film solar cells. It should be noted that if the concentration of Pb(SCN)\textsubscript{2} additives exceeds 1.5 mol %, the solvent annealing cannot fully avoid the formation of excessive PbI\textsubscript{2}. Figure S9a shows a SEM image of a FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} perovskite thin film processed with combined 2.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing. The formation of PbI\textsubscript{2} nanorods is clearly evident, though the amount of PbI\textsubscript{2} nanorods is lower than that of the film processed with only 2.0 mol % Pb(SCN)\textsubscript{2} additive (Figure S3e). The XRD patterns shown in Figure S9b confirm the reduced amount of PbI\textsubscript{2} in the film processed with combined 2.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing compared to that in the film processed with only 2.0 mol % Pb(SCN)\textsubscript{2} additive. The SEM images (Figure S9a and Figure S3e) show that the average grain size of the FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} perovskite film processed by the combined 2.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing is much larger than the film with 1.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing (1944 \pm 775 vs 1036 \pm 111 nm), but the solar cells based on the former films exhibited much lower average PCEs (Figure S9c), that is, 13.82 (11.67)% when measured under reverse (forward) voltage scans, than the solar cells made of the latter FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} perovskite thin films. We found that the optimal concentration of Pb(SCN)\textsubscript{2} additive is 1.0–1.5 mol % for the combined Pb(SCN)\textsubscript{2} additive and solvent annealing process.

We have fabricated a large number of solar cells, over 40 cells for 0% Pb(SCN)\textsubscript{2}, 0% Pb(SCN)\textsubscript{2} + SA, and 1% Pb(SCN)\textsubscript{2} and over 80 cells for 1% Pb(SCN)\textsubscript{2} + SA FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} perovskite thin films. The statistics of all device photovoltaic parameters including V\textsubscript{oc}, J\textsubscript{sc}, FF, and PCE are shown in Figure 2a–d, respectively. The average device photovoltaic parameters are listed in Table S2. The statistics show a very clear trend: all device performance parameters improve from 0% Pb(SCN)\textsubscript{2} to 0% Pb(SCN)\textsubscript{2} + SA to 1% Pb(SCN)\textsubscript{2} and to 1% Pb(SCN)\textsubscript{2} + SA. The FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} thin films with the combined 1.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing show an average PCE of 17.68 \pm 0.36 (15.58 \pm 0.55)% with an average V\textsubscript{oc} of 1.23 \pm 0.01 (1.16 \pm 0.03) V, an average J\textsubscript{sc} of 18.51 \pm 0.06 (18.51 \pm 0.06) mA cm\textsuperscript{−2}, and an average FF of 77.78 \pm 1.39 (72.45 \pm 1.62) when measured under reverse (forward) voltage scans. Compared with the devices without Pb(SCN)\textsubscript{2} additive and solvent annealing, the average V\textsubscript{oc}, J\textsubscript{sc}, and FF are increased by 6.96 (6.42), 6.69 (6.56), and 15.14 (17.14)% respectively, when measured under reverse (forward) voltage scans. As a result, the PCE is increased by 31.55 (32.60)%.

Figure 3a shows the current density–voltage (J–V) curves of the best-performing FA\textsubscript{0.8}Cs\textsubscript{0.2}Pb(I\textsubscript{0.7}Br\textsubscript{0.3})\textsubscript{3} thin-film solar cell fabricated using the combined 1.0 mol % Pb(SCN)\textsubscript{2} additive and solvent annealing. The cell demonstrates a PCE of 18.27 (16.62)% with a V\textsubscript{oc} of 1.25 (1.21) V, a J\textsubscript{sc} of 18.53 (18.54) mA cm\textsuperscript{−2}, and a FF of 78.95 (74.40)% measured under reverse (forward) voltage scan. The V\textsubscript{oc} deficit of this device is 0.50
The smallest value for wide-bandgap perovskite solar cells with similar bandgap values. The $J_{sc}$ obtained from the $J-V$ curves are consistent with the value ($17.98 \text{ mA cm}^{-2}$) determined by integrating the measured external quantum efficiency (EQE) curve (Figure 3b) and the AM1.5G (100 mW cm$^{-2}$) solar spectrum. This device showed a stabilized PCE of 17.18% measured using the maximum power point tracking (MPPT) method, a record stabilized PCE for wide-bandgap perovskite solar cells with similar bandgap values.

Because all of our perovskite solar cells used the same cell configuration, including the ESL and HSL, we anticipate that the improvements in device performance caused by the combined 1.0 mol % Pb(SCN)$_2$ additive and solvent annealing process originated from the improved quality of the perovskite absorber layers. We carried out detailed characterizations to confirm this anticipation using time-resolved photoluminescence (TRPL) and EQE. Figure 4a shows the TRPL decays of FA$_{0.8}$Cs$_{0.2}$Pb(I$_{0.7}$Br$_{0.3}$)$_3$ thin films processed with different conditions: 0% Pb(SCN)$_2$, 0% Pb(SCN)$_2$ + SA, 1% Pb(SCN)$_2$, and 1% Pb(SCN)$_2$ + SA. For these measurements, the perovskite films were coated with thin layers of poly(methyl methacrylate) (PMMA) to protect the film surfaces and reduce surface recombination. PL decay curves were biexponential in nature and were fitted by iterative deconvolution with the measured system response function. The mean carrier lifetimes for the biexponential fit were calculated by the weighted average method and are listed in Table S3. These four samples have mean carrier lifetimes of 332, 546, 631, and 1081 ns, of
which the trend correlates very well with the trend of their average grain sizes (66 ± 24, 227 ± 103, 363 ± 111, and 1036 ± 318 nm) as measured from the SEM images (Figure 1). The TRPL results suggest that the increased carrier lifetime is mainly caused by the reduced density of grain boundary regions that can be trap centers. The EQE curves obtained from solar cells made of FA$_{0.8}$Cs$_{0.2}$Pb(I$_{0.7}$Br$_{0.3}$)$_3$ thin films processed with different conditions (0% Pb(SCN)$_2$, 0% Pb(SCN)$_2$ + SA, 1% Pb(SCN)$_2$, and 1% Pb(SCN)$_2$ + SA) are shown in Figure 4b. As indicated by the box (purple dash line), the main differences among these EQE curves are at the longer wavelength regions of 600–720 nm. The device with 1% Pb(SCN)$_2$ + SA shows higher EQE values in these regions than the devices with 0% Pb(SCN)$_2$, 0% Pb(SCN)$_2$ + SA, 1% Pb(SCN)$_2$, and 1% Pb(SCN)$_2$. A longer wavelength indicates a deeper location (closer to the HSL/Au interface) for charge carrier generation. The photogenerated electrons must travel a longer distance before they can be collected. Therefore, a higher EQE value in the longer wavelength region confirms a lower carrier recombination rate. Thus, the EQE results shown in Figure 4b are consistent with the TRPL results shown in Figure 4a. In summary, we have demonstrated the synergistic effects of Pb(SCN)$_2$ additive and solvent annealing on the performances of wide-bandgap mixed-cation lead mixed-halide perovskite solar cells. We found that the combination of 1.0 mol % Pb(SCN)$_2$ additive and solvent annealing can significantly increase the grain size of wide-bandgap FA$_{0.8}$Cs$_{0.2}$Pb(I$_{0.7}$Br$_{0.3}$)$_3$ perovskite thin films as compared to the films without Pb(SCN)$_2$ additive and without solvent annealing (66 ± 24 nm vs 1036 ± 111 nm) and also avoids the formation of excessive PbI$_2$, which is an inevitable biproduct of the solvent annealing-free Pb(SCN)$_2$ additive process. The best-performing wide-bandgap perovskite solar cell with a bandgap of 1.75 eV achieves a stabilized PCE of 17.18%.
